20 **Abstract**

Rising production costs and declining commodity prices have motivated farmers to seek computational tools for optimizing resource application. This paper presents a generalized, coupled ordinary differential equation (ODE) model for crop growth that captures the nonlinear dynamics of plant development under varying environmental conditions and fertilizer and irrigation strategy. The model tracks five state variables—plant height, leaf area, number of leaves, flower size, and fruit biomass—each governed by logistic growth with time-varying growth rates and carrying capacities. These parameters are modulated by nutrient factors that quantify how well actual water, fertilizer, temperature, and solar radiation levels match expected values. To capture the delayed physiological response of plants to resource inputs, we employ finite impulse response (FIR) convolution with Gaussian kernels, where different temporal spreads represent the distinct metabolic timescales for each input type. Cumulative divergence from expected nutrient levels is tracked using exponential moving average filters, providing the model with memory of past stress events. Given this nonlinear, delay-affected system, we employ a genetic algorithm (GA) to discover optimal irrigation and fertilizer strategies that maximize crop yield while minimizing input costs. The GA searches over application frequency and amount for both irrigation and fertilizer, evaluating candidate strategies through full-season simulations. We demonstrate the framework using corn grown in Fairfax, Iowa, with historical weather data. Results show the GA identifies non-intuitive strategies that outperform conventional uniform application schedules, achieving 16%

higher net revenue through strategic timing of resource inputs. The optimized strategies use dramatically less irrigation than farmer best practices while achieving higher crop yields, demonstrating that under delayed absorption dynamics, timing of inputs matters more than total quantity.

22 model, genetic algorithm, cumulative stress tracking

---

## 23 1. Introduction

24 The agriculture sector in the United States faces significant challenges as  
25 the number of farms declines and the cost of farming continues to rise [? ].  
26 Rising production expenses for equipment, seeds, and labor, coupled with  
27 elevated interest rates and declining commodity prices, have made farming  
28 increasingly expensive. To navigate this challenging landscape, farmers are  
29 employing strategies such as cost management and operational optimization.  
30 One promising approach is to use modeling and simulation to optimize farm  
31 operations without substantial capital investment. Recent advances in com-  
32 putational methods have enabled sophisticated digital-twin frameworks for  
33 precision agriculture [? ? ], and machine learning techniques have been  
34 applied to optimize sensor placement and resource delivery in agricultural  
35 systems [? ? ].

36 Mathematical modeling of crop growth has a rich history, with models  
37 ranging from simple empirical relationships to complex mechanistic simula-  
38 tions. Logistic growth models, first proposed by Verhulst in 1838, remain  
39 widely used due to their interpretability and ability to capture resource-  
40 limited growth dynamics [? ]. More sophisticated crop models such as  
41 DSSAT [? ], APSIM [? ], and WOFOST [? ] simulate detailed physio-  
42 logical processes but require extensive parameterization and may be compu-  
43 tationally expensive for optimization applications. In contrast, reduced-order  
44 models that capture essential dynamics while remaining tractable for opti-  
45 mization have gained attention in precision agriculture [? ].

46 Optimization of irrigation and fertilizer application has been studied us-  
47 ing various approaches, including linear and nonlinear programming [? ],  
48 dynamic programming [? ], and metaheuristic algorithms [? ]. Genetic algo-  
49 rithms (GAs) are particularly well-suited for this domain because they can  
50 handle nonlinear, non-convex objective functions and do not require gradi-  
51 ent information [? ]. Previous work has applied GAs to irrigation scheduling

[?] and fertilizer optimization [?], but these studies often use simplified plant response models that do not capture the delayed, cumulative effects of resource application.

This paper presents a generalized, coupled ordinary differential equation (ODE) model for crop growth that addresses these limitations. The model captures: (1) nonlinear logistic growth with state-dependent carrying capacities, (2) delayed absorption of water, fertilizer, temperature, and solar radiation inputs through finite impulse response (FIR) convolution, (3) cumulative stress tracking via exponential moving average (EMA) filters, and (4) coupling between vegetative and reproductive growth stages. The model is designed to enable global optimization under delayed, resource-coupled dynamics—a regime where even well-established management practices may benefit from computational refinement due to the sheer number of possible scheduling combinations.

We demonstrate the framework by optimizing irrigation and fertilizer strategies for corn, the most widely planted crop in the United States by acreage. Using a genetic algorithm, we search for strategies that maximize net revenue (crop value minus input costs) over a growing season. The approach is validated using historical weather data from Fairfax, Iowa, a representative location in the Corn Belt.

## 2. Generalized, coupled-ODE crop model

The proposed model tracks five state variables representing key aspects of plant development: plant height  $h$  (m), leaf area per leaf  $A$  (m<sup>2</sup>), number of leaves  $N$ , flower size  $c$  (number of spikelets), and fruit biomass  $P$  (kg). Each state variable follows logistic growth dynamics with time-varying growth rates and carrying capacities that depend on environmental conditions and resource availability.

The model receives four input signals: water from irrigation  $w$  (inches), fertilizer application  $f$  (lbs), ambient temperature  $T$  (°C), and solar radiation  $R$  (W/m<sup>2</sup>). Precipitation  $S$  (inches) is added to irrigation to obtain total water input. Temperature and radiation data are obtained from the National Solar Radiation Database (NSRDB) [?], while precipitation data comes from NOAA historical records [?].

85 *2.1. Delayed absorption via FIR convolution*

86 Plants do not immediately process applied nutrients; instead, there is  
 87 a physiologically-mediated delay between application and utilization. We  
 88 model this delayed absorption using finite impulse response (FIR) convolu-  
 89 tion with Gaussian kernels.

90 If cumulative nutrient uptake follows a sigmoid trajectory—with slow ini-  
 91 tial uptake due to transport lag, rapid increase once metabolic pathways acti-  
 92 vate, and eventual saturation—then instantaneous absorption rate follows a  
 93 bell-shaped curve. A Gaussian kernel is the least assumptive choice for a bell  
 94 curve, requiring only two parameters: the temporal spread  $\sigma$  (characterizing  
 95 absorption duration) and the peak delay  $\mu$ .

96 Given only the temporal spread  $\sigma$  for each nutrient type, we determine  $\mu$   
 97 such that 95% of the kernel mass lies within  $[0, 2\mu]$ . This requires solving

$$\text{erf}\left(\frac{\mu}{\sigma\sqrt{2}}\right) = 0.95, \quad (1)$$

98 which yields  $\mu \approx 1.96\sigma$ . The Gaussian FIR kernel is then

$$g[k] = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left\{-\frac{1}{2} \frac{(k - \mu)^2}{\sigma^2}\right\}. \quad (2)$$

99 The FIR horizon  $L^*$  is chosen as the minimum length capturing 95% of  
 100 the kernel mass:

$$L^* = \min_L \left\{ L : \frac{\sum_{k=0}^{L-1} g[k]}{\sum_{k=0}^{K-1} g[k]} \geq 0.95 \right\} \quad (3)$$

101 where  $K$  is the simulation length in hours.

102 Different nutrients have different metabolic timescales. We use  $\sigma_w = 30$   
 103 hours for water (rapid uptake),  $\sigma_f = 300$  hours for fertilizer (slow uptake re-  
 104 flecting root absorption dynamics), and  $\sigma_T = \sigma_R = 30$  hours for temperature  
 105 and radiation (immediate physiological effects with short memory).

106 *2.2. Cumulative stress tracking via EMA filtering*

107 While FIR convolution captures delayed absorption, plants also accumu-  
 108 late stress from sustained deviations from optimal conditions. We model this  
 109 cumulative effect using exponential moving average (EMA) filters, which are  
 110 equivalent to first-order infinite impulse response (IIR) systems.

111 The EMA filter with memory parameter  $\beta \in [0, 1)$  has the recursive form:

$$y[k] = (1 - \beta)x[k] + \beta y[k - 1] \quad (4)$$

112 where larger  $\beta$  values correspond to longer memory (slower response to  
113 changes). This formulation preserves constant signals ( $x[k] = c$  implies  
114  $y[k] \rightarrow c$ ) while smoothing transient fluctuations.

### 115 2.3. Nutrient factor calculation

116 We now describe the complete transformation pipeline that converts raw  
117 input signals into nutrient factors  $\nu \in [0, 1]$  that modulate plant growth. Us-  
118 ing fertilizer as an example (the same process applies to water, temperature,  
119 and radiation):

120 **Step 1: Delayed absorption.** Convolve the raw fertilizer signal  $f[k]$   
121 with the Gaussian FIR kernel:

$$\bar{f}[k] = \sum_{n=0}^{L_f-1} g_f[n] f[k - n] \quad (5)$$

122 **Step 2: Cumulative absorption.** Compute the running sum of ab-  
123 sorbed fertilizer:

$$F[k] = \sum_{n=0}^k \bar{f}[n] \quad (6)$$

124 **Step 3: Instantaneous anomaly.** Compare actual cumulative absorp-  
125 tion to expected levels:

$$\delta_f[k] = \left| \frac{k \cdot f_{\text{typ}} - F[k]}{k \cdot f_{\text{typ}} + \epsilon} \right| \quad (7)$$

126 where  $f_{\text{typ}}$  is the typical hourly fertilizer level the plant “expects” and  $\epsilon$  is a  
127 small constant preventing division by zero.

128 **Step 4: Cumulative divergence.** Apply EMA smoothing to track  
129 sustained anomalies:

$$\Delta_f[k] = \beta_\Delta \Delta_f[k - 1] + (1 - \beta_\Delta) \delta_f[k] \quad (8)$$

130 where  $\beta_\Delta = 0.95$  provides long memory.

131     **Step 5: Nutrient factor.** Convert divergence to a stress factor via  
 132 exponential decay with additional EMA smoothing:

$$\nu_f[k] = \beta_\nu \nu_f[k-1] + (1 - \beta_\nu) \exp\{-\alpha \Delta_f[k]\} \quad (9)$$

133 where  $\alpha = 3$  ensures  $\nu \approx 0.05$  when  $\Delta = 1$  (complete divergence from  
 134 expected levels), and  $\beta_\nu = 0.05$ .

135     The nutrient factor  $\nu_f[k]$  equals 1 when fertilizer application perfectly  
 136 matches expected levels and decays toward 0 under sustained over- or under-  
 137 application. This captures the intuition that plants are resilient to brief  
 138 deviations but suffer cumulative damage from prolonged stress.

139     Figure ?? illustrates the FIR convolution and EMA smoothing operations  
 140 that constitute the metabolic transformation pipeline. The left panel shows  
 141 how the Gaussian FIR kernel spreads and delays input signals, while the  
 142 right panel demonstrates how EMA filtering with different  $\beta$  values tracks  
 143 cumulative divergence with varying memory lengths.

144 *2.4. Effects of inputs on plant growth*

145 Different inputs affect different aspects of plant growth. Tables ?? and  
 146 ?? summarize these relationships based on agronomic literature [? ? ? ].

State variable	Irrigation on growth rate	Fertilizer on growth rate	Irrigation on capacity	Fertilizer on capacity
Plant height $h$	$\sim$	+	$\sim$	+
Leaf area $A$	$\sim$	+	+	+
Number of leaves $N$	$\sim$	$\sim$	$\sim$	$\sim$
Flower size $c$	$\sim$	$\sim$	+	$\sim$
Fruit biomass $P$	$\sim$	$\sim$	+	+

Table 1: Effects of irrigation and fertilizer on growth dynamics. “+” indicates positive effect, “ $\sim$ ” indicates a negligible effect.

State variable	Temp. on growth rate	Temp. on capacity	Radiation on growth rate	Radiation on capacity
Plant height $h$	+	+	+	+
Leaf area $A$	+	+	+	+
Number of leaves $N$	$\sim$	+	$\sim$	+
Flower size $c$	–	–	–	–
Fruit biomass $P$	+	+	+	+

Table 2: Effects of temperature and solar radiation on growth dynamics. “+” indicates positive effect, “ $\sim$ ” indicates a negligible effect, “–” indicates a negative effect. For flower size, excess heat and radiation reduce flower development, hence negative effects.

147 *2.5. Growth dynamics*

148 Each state variable follows logistic growth with time-varying parameters  
 149 modulated by nutrient factors. The general form is:

$$\frac{dx}{dt} = \hat{a}_x(t) \cdot x(t) \left( 1 - \frac{x(t)}{\hat{k}_x(t)} \right) \quad (10)$$

150 where  $\hat{a}_x(t)$  is the effective growth rate and  $\hat{k}_x(t)$  is the effective carrying  
 151 capacity, both functions of the nutrient factors.

152 The effective parameters are computed as geometric means of the relevant  
 153 nutrient factors, reflecting multiplicative rather than additive effects. This  
 154 choice is motivated by the observation that growth rates compound over  
 155 time, making geometric averaging appropriate [? ].

156 **Plant height** responds to fertilizer, temperature, and radiation:

$$\hat{a}_h(t) = a_h(\nu_f \nu_T \nu_R)^{1/3}, \quad \hat{k}_h(t) = k_h(\nu_f \nu_T \nu_R)^{1/3} \quad (11)$$

157 **Leaf area** additionally depends on water and is coupled to height:

$$\hat{a}_A(t) = a_A(\nu_f \nu_T \nu_R)^{1/3}, \quad \hat{k}_A(t) = k_A \left( \nu_w \nu_f \nu_T \nu_R \frac{\hat{k}_h}{k_h} \right)^{1/5} \quad (12)$$

158 **Number of leaves** depends only on temperature and radiation through  
 159 the carrying capacity:

$$\hat{a}_N(t) = a_N, \quad \hat{k}_N(t) = k_N(\nu_T \nu_R)^{1/2} \quad (13)$$

160 **Flower size** (spikelet count) exhibits inverse dependence on temperature  
 161 and radiation—excess heat and light reduce flowering:

$$\hat{a}_c(t) = a_c \left( \frac{1}{\nu_T} \frac{1}{\nu_R} \right)^{1/2}, \quad \hat{k}_c(t) = k_c \left( \nu_w \frac{1}{\nu_T} \frac{1}{\nu_R} \right)^{1/3} \quad (14)$$

162 **Fruit biomass** depends on all inputs and is coupled to vegetative growth:

$$\hat{a}_P(t) = a_P \left( \frac{1}{\nu_T} \frac{1}{\nu_R} \right)^{1/2}, \quad \hat{k}_P(t) = k_P \left( \nu_w \nu_f \nu_T \nu_R \frac{\hat{k}_h}{k_h} \frac{\hat{k}_A}{k_A} \frac{\hat{k}_c}{k_c} \right)^{1/7} \quad (15)$$

163 The coupling terms  $\hat{k}_h/k_h$ ,  $\hat{k}_A/k_A$ , and  $\hat{k}_c/k_c$  encode physiological depen-  
 164 dencies: taller plants with more leaf area can support larger fruit, while larger  
 165 tassels (more spikelets) may compete with ear development.

## 166 2.6. Model parameters

167 The baseline growth rates and carrying capacities are crop-specific pa-  
 168 rameters that can be estimated from field data or literature values. For corn,  
 169 we use the values in Table ??, calibrated to match typical development time-  
 170 lines where plants reach full vegetative size around 65–70 days after sowing  
 171 and grain fill completes around 125 days [? ].

State	Growth rate	Carrying capacity	Initial condition	Units
Height $h$	$a_h = 0.010 \text{ hr}^{-1}$	$k_h = 3.0$	$h_0 = 0.001$	m
Leaf area $A$	$a_A = 0.0105 \text{ hr}^{-1}$	$k_A = 0.65$	$A_0 = 0.001$	m <sup>2</sup>
Leaves $N$	$a_N = 0.011 \text{ hr}^{-1}$	$k_N = 20$	$N_0 = 0.001$	count
Spikelets $c$	$a_c = 0.010 \text{ hr}^{-1}$	$k_c = 1000$	$c_0 = 0.001$	count
Fruit $P$	$a_P = 0.005 \text{ hr}^{-1}$	$k_P = 0.25$	$P_0 = 0.001$	kg

Table 3: Baseline model parameters for corn. Growth rates are per hour; initial conditions are set to  $k_x/K$  where  $K \approx 2900$  is the season length in hours.

### 172 3. Simulation

173 The logistic ODE admits a closed-form solution, enabling exact time-  
174 stepping without numerical integration error. Given state  $x(t)$  at time  $t$ , the  
175 state at  $t + \Delta t$  is:

$$x(t + \Delta t) = \frac{\hat{k}_x(t)}{1 + \left( \frac{\hat{k}_x(t)}{x(t)} - 1 \right) \exp(-\hat{a}_x(t)\Delta t)} \quad (16)$$

176 where  $\hat{a}_x(t)$  and  $\hat{k}_x(t)$  are treated as constant over the time step. This closed-  
177 form approach is more accurate than forward Euler integration and avoids  
178 instability issues that can arise with explicit methods at larger time steps.

179 We simulate the growing season at hourly resolution ( $\Delta t = 1$  hour),  
180 yielding approximately 2900 time steps for a typical corn season (late April  
181 to early October). At each step, we: (1) update the nutrient factors based on  
182 cumulative inputs and divergences, (2) compute effective growth rates and  
183 carrying capacities, and (3) advance each state variable using Equation ??.

### 184 4. Optimization via genetic algorithm

185 Given the nonlinear, delay-affected dynamics of the crop model, gradient-  
186 based optimization is challenging. The delayed effects of inputs create a  
187 non-convex landscape with potentially many local optima. We therefore  
188 employ a genetic algorithm (GA), a population-based metaheuristic inspired  
189 by natural selection that can effectively explore complex search spaces [? ].

190 *4.1. Decision variables*

191 Each candidate solution encodes a complete irrigation and fertilization  
192 strategy as a four-dimensional vector:

$$\mathbf{u} = \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{bmatrix} = \begin{bmatrix} \text{irrigation frequency (hours)} \\ \text{irrigation amount (inches)} \\ \text{fertilizer frequency (hours)} \\ \text{fertilizer amount (lbs)} \end{bmatrix} \quad (17)$$

193 The frequencies specify application intervals:  $u_1 = 168$  means irrigate  
194 every 168 hours (weekly). The amounts specify the quantity applied at  
195 each event. This parameterization assumes regular, periodic application—a  
196 simplification that captures common agricultural practice while keeping the  
197 search space tractable.

198 *4.2. Objective function*

199 The objective is to maximize net revenue, defined as crop value minus  
200 input costs.

$$\text{Revenue}(\mathbf{u}) = \text{Crop Value} - \text{Input Costs} \quad (18)$$

201 The crop value depends on final plant state at harvest:

$$\text{Crop Value} = \omega_h h[K] + \omega_A A[K] + \omega_P P[K] \quad (19)$$

202 where  $K$  is the final time step and  $\omega_h$ ,  $\omega_A$ ,  $\omega_P$  are economic weights (dollars  
203 per unit) for height, leaf area, and fruit biomass respectively.

204 The input costs accumulate over the season:

$$\text{Input Costs} = \omega_w \sum_{k=0}^K w[k] + \omega_f \sum_{k=0}^K f[k] \quad (20)$$

205 where  $\omega_w$  and  $\omega_f$  are costs per unit of irrigation and fertilizer.

206 For corn, the economic weights are derived from market prices and typical  
207 yields (Table ??). The fruit biomass weight dominates, reflecting that grain  
208 yield is the primary economic output.

Parameter	Value	Derivation
$\omega_w$	\$2.00/inch	Typical irrigation cost
$\omega_f$	\$0.61/lb	Weighted NPK cost
$\omega_h$	\$35/m	Silage value proxy
$\omega_A$	\$215/m <sup>2</sup>	Silage value proxy
$\omega_P$	\$4,450/kg	\$4/bushel $\times$ plant density

Table 4: Economic weights for the corn objective function. The fruit biomass weight accounts for approximately 28,350 plants per acre at \$0.157/kg.

### 209 4.3. Algorithm description

210 The GA maintains a population of  $M$  candidate solutions and iteratively  
211 improves them through selection, crossover, and mutation over  $G$  genera-  
212 tions. Algorithm ?? presents the complete procedure.

213 **Selection.** After each generation, population members are ranked by  
214 cost. The top  $P$  members survive as “parents” for the next generation. This  
215 selection ensures the best solutions are never lost.

216 **Crossover.** New “children” are created by blending two parent solutions.  
217 For each child, we randomly select two parents and compute a weighted  
218 average:

$$\mathbf{u}^{(\text{child})} = \phi \cdot \mathbf{u}^{(a)} + (1 - \phi) \cdot \mathbf{u}^{(b)} \quad (21)$$

219 where  $\phi \sim \text{Uniform}(0, 1)$  under normal operation. This crossover can produce  
220 children anywhere along the line segment connecting the parents, enabling  
221 smooth exploration of the search space.

222 **Mutation and Diversity.** To maintain population diversity and escape  
223 local optima, the remaining  $M - P - C$  population slots are filled with ran-  
224 domly generated solutions. Additionally, if the best cost stagnates (changes  
225 by less than 0.01) for 10 consecutive generations, we switch to aggressive  
226 crossover with  $\phi \sim \text{Uniform}(-1, 2)$ . This allows children to lie outside the  
227 convex hull of their parents, promoting exploration of new regions.

228 **Default Parameters.** We use  $M = 128$  members,  $P = 16$  parents,  
229  $C = 16$  children, and  $G = 100$  generations. The large population relative  
230 to generations ensures diversity for exploration while preventing premature  
231 convergence.

## 232 5. Case study: corn in iowa

233 We demonstrate the framework using corn, the most widely planted crop  
 234 in the United States with over 90 million acres harvested annually [? ].  
 235 The case study uses historical weather data from Fairfax, Iowa (41.76°N,  
 236 91.87°W), a representative location in the Corn Belt (USDA climate zones  
 237 4b–5b).

### 238 5.1. Scenario configuration

239 The simulation covers a typical growing season from late April to early  
 240 October (approximately 2900 hours). Environmental inputs are:

- 241 • **Temperature and radiation:** Hourly data from NSRDB for Fairfax,  
 242 IA. Mean temperature is 22.8°C; mean solar radiation is 580 W/m<sup>2</sup>.
- 243 • **Precipitation:** Daily data from NOAA, interpolated to hourly reso-  
 244 lution.
- 245 • **Typical nutrient expectations:** Based on agronomic recommenda-  
 246 tions [? ], the model expects 28 inches of water and 355 lbs of NPK  
 247 fertilizer over the season ( $w_{\text{typ}} \approx 0.01$  in/hr,  $f_{\text{typ}} \approx 0.12$  lb/hr).

248 Table ?? summarizes expected corn development timelines used to cali-  
 249 brate model parameters.

State variable	Days to maturity	Hours to maturity	Typical final value
Plant height $h$	65–70	1560–1680	2.7–3.7 m
Leaf area $A$	55–65	1320–1560	0.6–0.7 m <sup>2</sup>
Number of leaves $N$	65	1560	18–20
Spikelets $c$	65–70	1560–1680	~1000
Fruit biomass $P$	125	3000	0.15–0.36 kg

Table 5: Corn development timeline and typical final values from agronomic literature [? ? ].

250 *5.2. Baseline scenario: farmer best practices under drought*

251 To establish a performance baseline, we first simulate crop growth under  
252 a drought scenario (50% of typical precipitation) using conventional farmer  
253 practices: weekly irrigation of 1 inch [?] and monthly fertilizer applications  
254 of 90 lbs [?]. These values reflect standard agronomic recommendations for  
255 corn in the Corn Belt region.

256 Figure ?? shows the environmental disturbances and control inputs over  
257 the growing season. The reduced precipitation characteristic of a drought  
258 year is clearly visible, along with the periodic irrigation and fertilizer appli-  
259 cations.

260 Figure ?? shows the resulting plant state trajectories. Under drought  
261 conditions with conventional management, the plant reaches the following  
262 final values: height of 2.6 m (vs. 3.0 m capacity), leaf area of 0.57 m<sup>2</sup> (vs.  
263 0.65 m<sup>2</sup>), and fruit biomass of 0.22 kg (vs. 0.25 kg). The net revenue under  
264 this baseline scenario is \$859/acre.

265     The baseline scenario demonstrates how the model captures stress ef-  
266     fects: despite regular irrigation, the mismatch between applied water and  
267     the plant’s metabolic expectations under drought conditions leads to sus-  
268     tained nutrient factor depression and reduced growth potential. Detailed  
269     visualizations of the applied vs. absorbed nutrients, cumulative values, and  
270     nutrient factors are provided in the Supplementary Information.

### 271 5.3. Optimization configuration

272 The GA searches over the following bounds:

- 273 • Irrigation frequency: 100–700 hours (4–29 days between applications)
- 274 • Irrigation amount: 0.5–5.0 inches per application
- 275 • Fertilizer frequency: 700–2900 hours (29–121 days, i.e., 1–4 applications  
276 per season)
- 277 • Fertilizer amount: 100–500 lbs per application

278 These bounds reflect practical constraints: irrigation systems have mini-  
279 mum application rates, and fertilizer is typically applied in a small number of  
280 large doses rather than continuously. The optimization was performed under  
281 the same environmental conditions: a drought scenario with 50% of typical  
282 precipitation.

### 283 5.4. Optimization results

284 To assess robustness of the optimization, we executed 10 independent  
285 GA runs with different random seeds. Figure ?? shows the convergence of  
286 all 10 runs, with each curve representing the best revenue achieved at each  
287 generation. All runs converge to similar final values (within 3% of each other),  
288 demonstrating that the GA reliably finds near-optimal solutions despite the  
289 stochastic nature of the search.

290 The optimal strategy identified by the GA is summarized in Table ??.  
291 Notably, the algorithm discovers a strategy with less frequent but larger  
292 irrigation events and infrequent fertilizer applications—a pattern that mini-  
293 mizes cumulative divergence from expected nutrient levels given the model’s  
294 delayed absorption dynamics.

Parameter	Optimal Value	Interpretation
Irrigation frequency	1237 hours	Every $\sim 7$ weeks
Irrigation amount	5 inches	Per application
Fertilizer frequency	803 hours	Every 33 days
Fertilizer amount	77 lbs	Per application

Table 6: Optimal irrigation and fertilization strategy identified by the GA.

295 Figure ?? shows the plant state trajectories for the best member in each  
296 of the 10 GA runs. All optimized strategies achieve substantially higher final  
297 values than the baseline farmer practices: fruit biomass ranges from 0.168–  
298 0.225 kg (vs. 0.22 kg baseline), heights reach 2.41–2.88 m (vs. 2.6 m), leaf  
299 areas reach 0.44–0.56 m<sup>2</sup> (vs. 0.57 m<sup>2</sup>), and revenues reach 778–999 \$/acre  
300 (vs. \$859/acre baseline). The consistency across runs further confirms the  
301 robustness of the optimization, and while the farmer best practice yields  
302 higher revenue than one GA run (run 2), in aggregate, the GA optimization  
303 meaningfully improved upon the baseline.

Table ?? provides an economic comparison between the baseline farmer practices and the GA-optimized strategies. The best GA strategy achieves \$999/acre net revenue compared to \$859/acre for the baseline—a 16% improvement. Even the worst members in each GA run’s final population outperform the baseline, providing a sanity check that random strategies are not viable (see Supplementary Information).

Metric	GA-Optimized	Baseline
Final fruit biomass	0.22 kg	0.22 kg
Final height	2.8 m	2.6 m
Final leaf area	0.60 m <sup>2</sup>	0.57 m <sup>2</sup>
Total irrigation	15 inches	18 inches
Total fertilizer	307 lbs	450 lbs
Crop value	\$1218	\$1171
Input costs	\$219	\$312
<b>Revenue</b>	<b>\$999</b>	<b>\$859</b>

Table 7: Economic comparison of GA-optimized versus baseline farmer strategies. The optimized strategy achieves 16% higher net revenue through both increased crop value and dramatically reduced irrigation costs.

## 6. Discussion

### 6.1. Interpretation of results

The GA-optimized strategy differs from conventional wisdom in several notable ways. The algorithm discovers that less frequent but larger irrigation events, combined with reduced total fertilizer input, can outperform conventional uniform application schedules. This counterintuitive result emerges from the model’s delayed absorption dynamics: under drought conditions, the plant’s metabolic expectations are calibrated to typical water availability. The GA discovers that strategically-timed resource inputs better maintain alignment with metabolic expectations than aggressive compensation for drought through frequent, uniform applications.

The consistency across 10 independent GA runs provides confidence that the optimization reliably identifies high-performing regions of the strategy space. While individual runs converge to somewhat different local optima (with revenues ranging from \$778 to \$983 per acre), 9 of 10 runs outperform

the baseline farmer practices, demonstrating the robustness of the optimization approach. The sanity check showing that even the worst members in each final population generally outperform baseline practices confirms that the GA successfully eliminates poor candidates.

The 16% revenue improvement (\$999 vs. \$859 per acre) demonstrates substantial potential value from model-based optimization. This improvement comes from two sources: (1) increased crop value due to better-aligned nutrient delivery, and (2) reduced input costs. The result suggests that conventional wisdom about drought response—applying more water to compensate—may be suboptimal when plant physiology involves delayed, cumulative-effect dynamics.

### 6.2. Parameter estimation in practice

The framework requires crop-specific parameters: growth rates, carrying capacities, metabolic timescales, and typical nutrient expectations. Several approaches could estimate these from data:

- **Growth curves:** Time-series imagery from field cameras or drones, processed with computer vision, could provide height and leaf area trajectories for fitting  $a_x$  and  $k_x$  parameters.
- **Metabolic timescales:** The temporal spreads  $\sigma$  could be estimated from controlled experiments varying input timing, or inferred from physiological literature on nutrient uptake rates.
- **Typical expectations:** Regional agronomic recommendations provide baseline values for  $w_{\text{typ}}$ ,  $f_{\text{typ}}$ ,  $T_{\text{typ}}$ , and  $R_{\text{typ}}$ .

Physics-informed neural networks (PINNs) could jointly fit model parameters and approximate unknown functional forms in the dynamics, potentially relaxing some of the structural assumptions in Section ??.

### 6.3. Limitations and extensions

Several model limitations suggest directions for future work:

**Growth model.** The logistic equation assumes symmetric growth around the inflection point. Richards growth [?] generalizes this with a shape parameter  $\nu$ :

$$\frac{dx}{dt} = a_x x \left[ 1 - \left( \frac{x}{k_x} \right)^\nu \right] \quad (22)$$

where  $\nu > 1$  produces steeper early growth (common in vegetative stages) and  $\nu < 1$  produces steeper late growth.

**Absorption kernels.** Gaussian kernels are symmetric, but physiological absorption often exhibits fast activation followed by slow decay. Log-normal or Gamma kernels could better capture this asymmetry.

**Saturation.** The current model does not explicitly limit nutrient uptake—all applied inputs eventually affect the plant. In reality, excess application may be lost to runoff or leaching. Saturating nonlinearities in the absorption pathway would provide a more realistic response to over-application.

**Spatial heterogeneity.** The model treats a single representative plant. Field-scale optimization would need to account for spatial variation in soil properties, microclimate, and plant density.

**Stochastic weather.** The case study uses historical weather data. Robust optimization under weather uncertainty, or adaptive strategies that respond to observed conditions, could improve real-world performance.

## 7. Conclusion

This paper presented a coupled ODE model for crop growth that captures delayed nutrient absorption via FIR convolution and cumulative stress effects via EMA filtering. The model’s time-varying growth rates and carrying capacities encode the intuition that plant development depends not just on current conditions but on the history of resource availability relative to physiological expectations.

Applied to corn optimization in Iowa under drought conditions, a genetic algorithm discovered irrigation and fertilizer strategies that achieve 16% higher net revenue than conventional farmer practices (\$999 vs. \$859 per acre). This improvement emerges from the model’s delayed absorption dynamics: strategic timing of inputs that aligns with metabolic expectations outperforms uniform application schedules. The consistency across 10 independent optimization runs, with 9 of 10 outperforming the baseline, confirms the robustness of these findings.

The framework is generalizable to other crops through re-parameterization and offers a computationally tractable approach to input optimization. Future work will extend the model to handle weather uncertainty, incorporate spatial heterogeneity, and validate predictions against field trial data.

## 390 8. Supplementary information

391 This supplementary section provides additional visualizations of the base-  
392 line scenario (farmer best practices under drought) and the GA optimization  
393 results.

### 394 *S1. Detailed baseline scenario analysis*

395 Figure ?? shows the applied versus absorbed nutrients under the baseline  
396 scenario. The delayed absorption via FIR convolution is clearly visible: the  
397 absorbed signals (smoothed curves) lag behind the applied inputs and exhibit  
398 the characteristic spreading effect of the Gaussian kernels.

399 Figure ?? shows the cumulative absorbed nutrients compared to expected  
400 (typical) levels. Under drought conditions, actual water absorption falls pro-  
401 gressively below expectations, while fertilizer, temperature, and radiation  
402 track more closely to typical values.

403 Figure ?? shows the instantaneous divergence from expected cumulative  
404 levels. These divergences, after EMA smoothing, determine the nutrient  
405 factors that modulate plant growth.

406 Figure ?? shows the resulting nutrient factors. The water factor  $\nu_w$  de-  
407 clines throughout the season as drought stress accumulates, reaching approx-  
408 imately 0.6 by harvest. This reduced water factor is the primary driver of  
409 the suboptimal crop growth observed in the baseline scenario.

410 *S2. GA optimization: worst-case analysis*

411 As a sanity check, Figure ?? shows the plant state trajectories for the  
412 *worst* member in each GA run’s final population. Even these subopti-  
413 mal strategies—the least fit survivors after 100 generations of evolution—  
414 outperform the baseline farmer practices. This confirms that: (1) the GA  
415 successfully eliminates poor strategies, and (2) random or arbitrary irri-  
416 gation/fertilization schedules cannot match even the worst optimized ap-  
417 proaches.

### Hourly Disturbances and Control Inputs

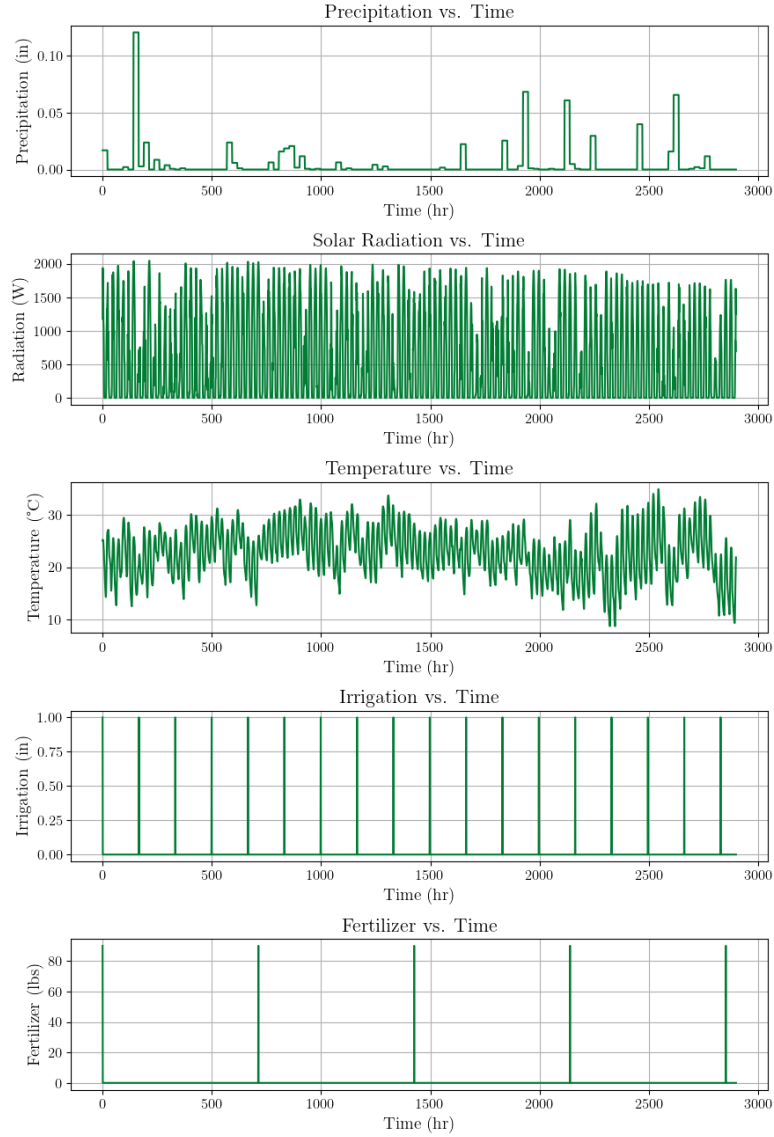

Figure 2: Environmental disturbances and control inputs for the baseline scenario. Top three panels show hourly precipitation (reduced to 50% of normal), solar radiation, and temperature from historical Iowa data. Bottom two panels show the farmer's irrigation (weekly, 1 inch) and fertilizer (monthly, 90 lbs) application strategy.

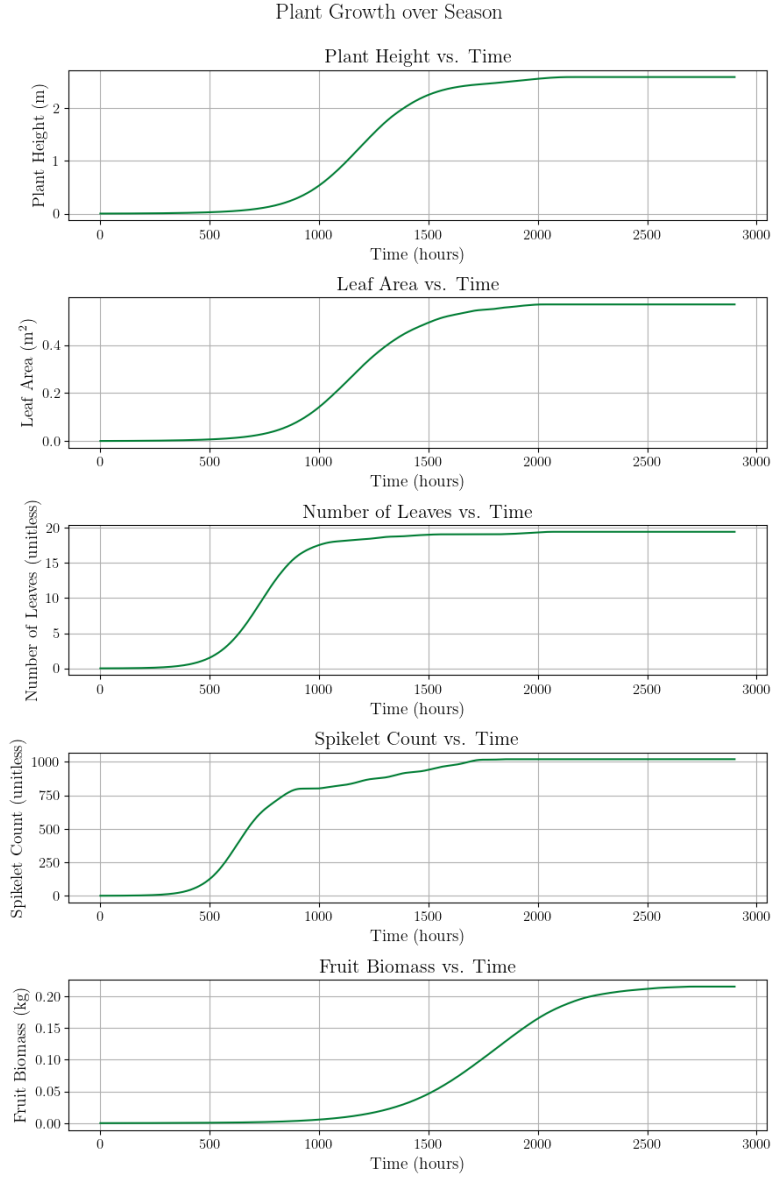

Figure 3: Plant state variable trajectories under the baseline scenario (farmer best practices during drought). All state variables reach suboptimal final values due to cumulative water stress. This strategy yields \$859/acre in revenue.

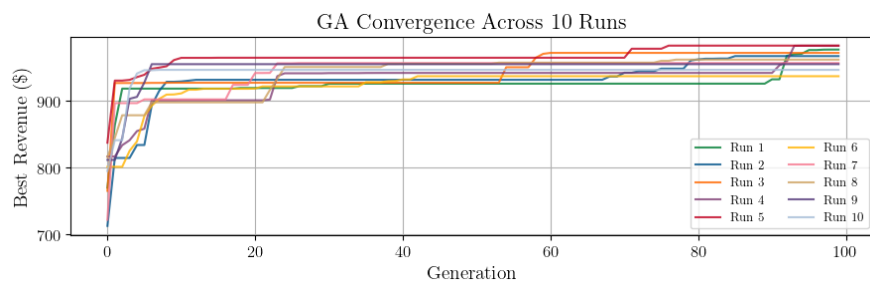

Figure 4: GA convergence across 10 independent runs. Each curve shows the best revenue at each generation. All runs exhibit rapid improvement in early generations followed by convergence to near-optimal solutions. The consistency across runs demonstrates algorithm robustness.

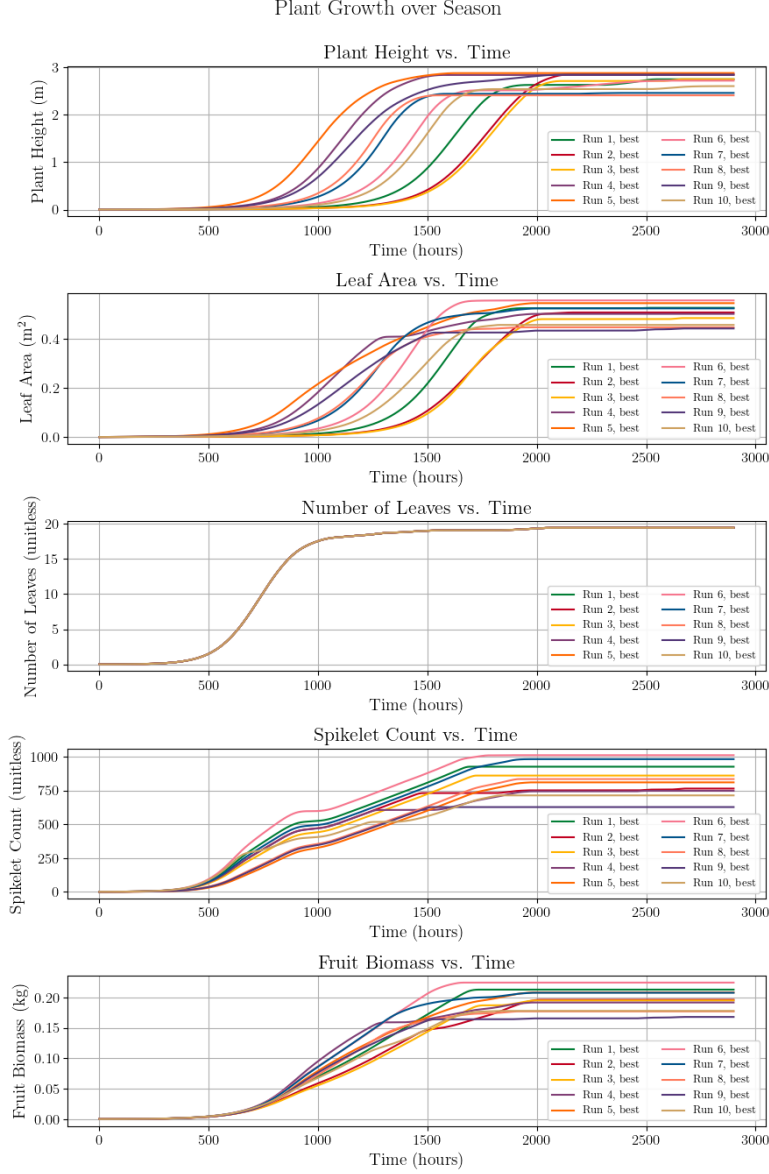

Figure 5: Plant state variable trajectories for the best member from each of the 10 independent GA runs. All optimized strategies achieve similar, near-optimal growth trajectories, and 9 of 10 runs substantially outperform the baseline farmer practices (Figure ??). The tight clustering of trajectories demonstrates that different GA runs converge to similar optimal strategies.

### Applied and Absorbed Inputs and Disturbances over Season

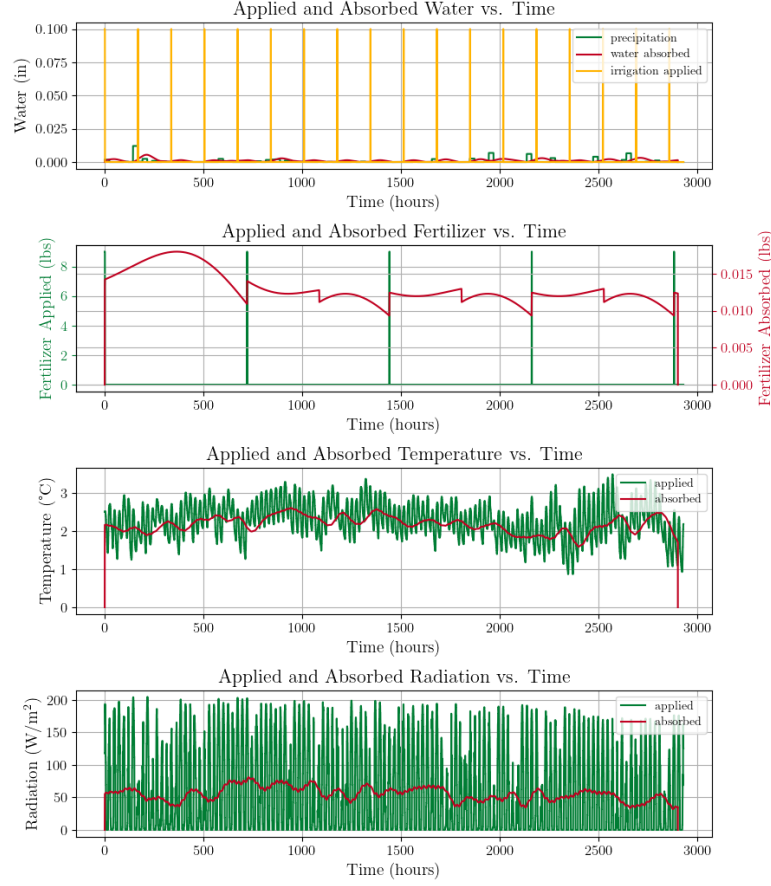

Figure 6: Applied versus absorbed nutrients under the baseline farmer strategy. The delayed absorption dynamics are evident in the lag between applied inputs and the smoothed absorbed signals. Water absorption ( $\sigma_w = 30$  hr) responds more quickly than fertilizer absorption ( $\sigma_f = 300$  hr).

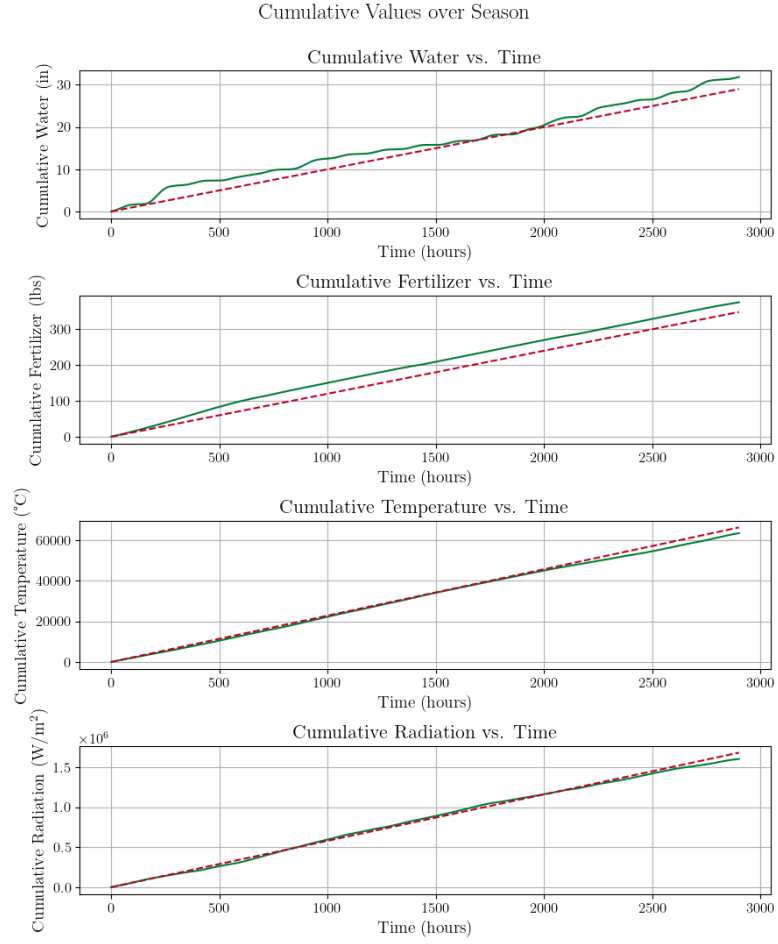

Figure 7: Cumulative absorbed nutrients (solid) versus expected levels (dashed red). The growing gap between actual and expected water absorption reflects the drought stress accumulating over the season. Fertilizer applications maintain closer alignment with expectations.

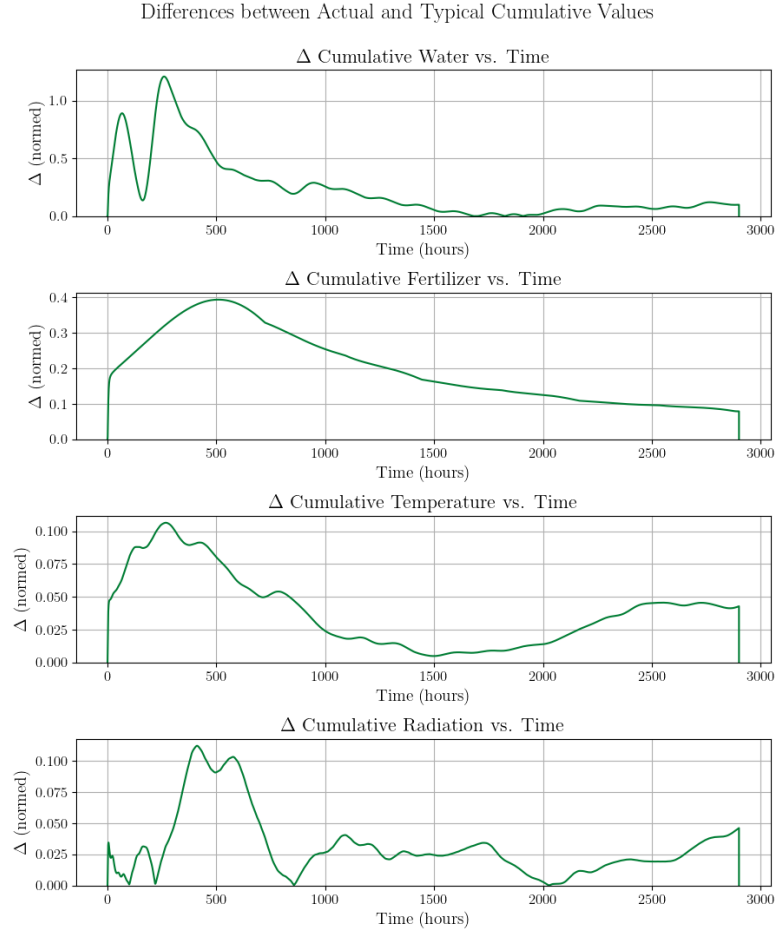

Figure 8: Instantaneous divergence from expected cumulative nutrient levels. Higher divergence indicates greater stress. The water divergence grows throughout the season due to cumulative drought effects.

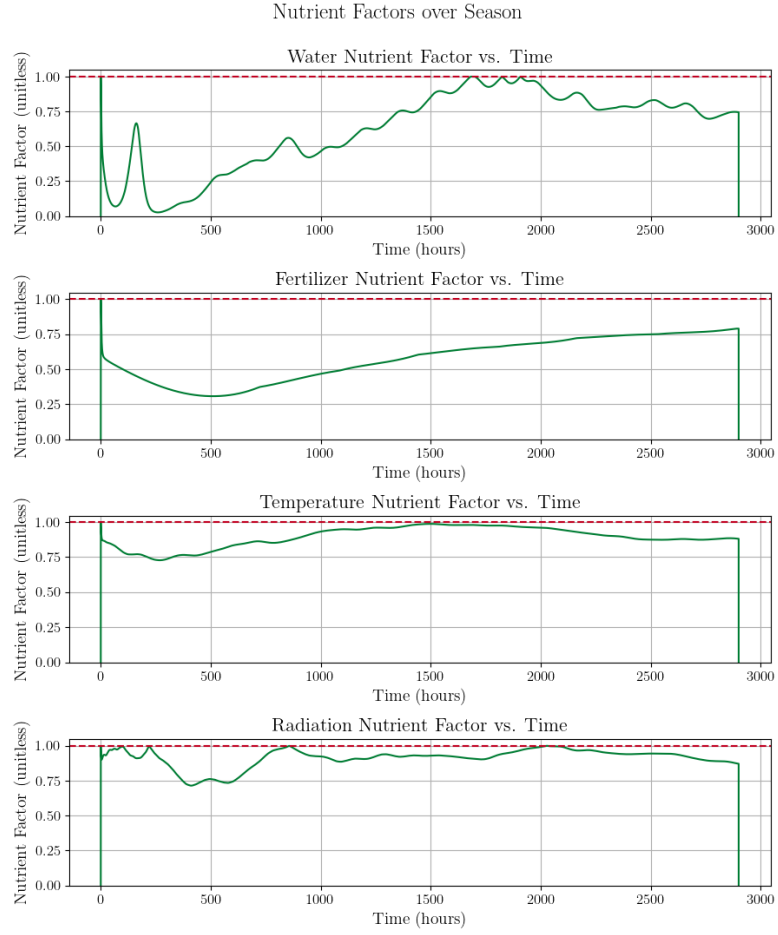

Figure 9: Nutrient factor evolution under the baseline scenario. The water factor  $\nu_w$  declines due to cumulative drought stress, while fertilizer, temperature, and radiation factors remain closer to 1.0 (no stress). The declining  $\nu_w$  reduces effective growth rates and carrying capacities throughout the season.

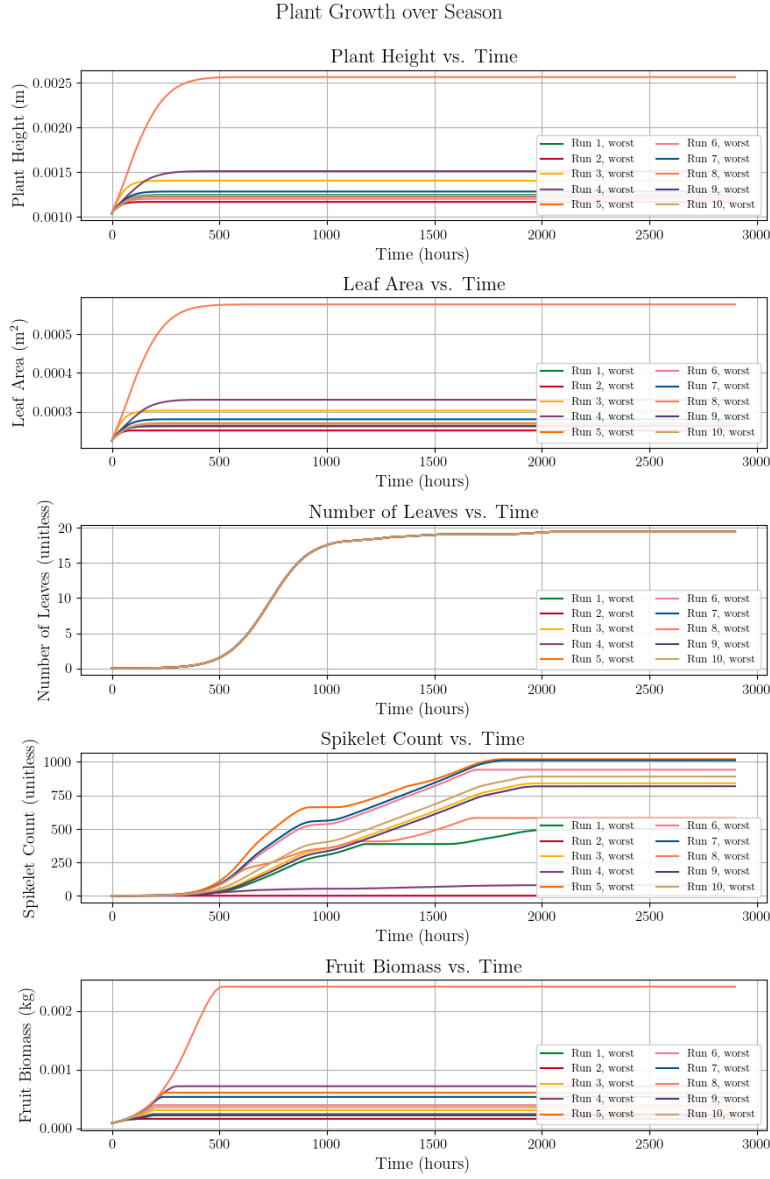

Figure 10: Plant state variable trajectories for the worst member from each GA run's final population. Even these suboptimal strategies outperform baseline farmer practices (compare to Figure ??), demonstrating that the GA successfully identifies the high-performing region of the strategy space and that random strategies are not competitive.
