Abstract

CONTEXT Rising production costs and declining commodity prices have motivated farmers to seek computational tools for optimizing resource application. While sophisticated crop models such as DSSAT and APSIM simulate detailed physiological processes, they require extensive parameterization and may be computationally expensive for optimization applications. Moreover, existing optimization approaches often use simplified plant response models that do not capture the delayed, cumulative effects of resource application.

OBJECTIVE This study develops a reduced-order crop growth model that captures delayed nutrient absorption dynamics and couples it with a genetic algorithm to optimize irrigation and fertilizer strategies that maximize net revenue while minimizing input costs.

METHODS We present a generalized, coupled ordinary differential equation (ODE) model tracking five state variables—plant height, leaf area, number of leaves, flower size, and fruit biomass—each governed by logistic growth with time-varying growth rates and carrying capacities. These parameters are modulated by nutrient factors quantifying how well actual water, fertilizer, temperature, and solar radiation levels match expected values. Delayed physiological response is captured using finite impulse response (FIR) convolution with Gaussian kernels, where different temporal spreads represent distinct metabolic timescales for each input type. Cumulative stress from sustained deviations is tracked using exponential moving average (EMA) filters.

A genetic algorithm searches over application frequency and amount for both irrigation and fertilizer, evaluating candidate strategies through full-season simulations. The framework is demonstrated using corn grown in Fairfax, Iowa, with historical weather data under a drought scenario (50% of typical precipitation).

RESULTS AND CONCLUSIONS The genetic algorithm identifies non-intuitive strategies that outperform conventional uniform application schedules, achieving 16% higher net revenue (\$999 vs. \$859 per acre) through strategic timing of resource inputs. The optimized strategies use 17% less irrigation (15 vs. 18 inches) and 32% less fertilizer (307 vs. 450 lbs) than farmer best practices while achieving comparable or higher crop yields. Across 10 independent optimization runs, 9 outperformed the baseline, demonstrating algorithm robustness.

SIGNIFICANCE These results demonstrate that under delayed absorption dynamics, timing of inputs matters more than total quantity—a finding that challenges conventional drought response strategies of increased irrigation frequency. The framework offers a computationally tractable alternative to complex mechanistic models for precision agriculture optimization and is generalizable to other crops through re-parameterization.

Keywords: precision agriculture, resource optimization, crop growth model, genetic algorithm, cumulative stress tracking

1. Introduction

The agriculture sector in the United States faces significant challenges as the number of farms declines and the cost of farming continues to rise [1]. Rising production expenses for equipment, seeds, and labor, coupled with elevated interest rates and declining commodity prices, have made farming increasingly expensive. To navigate this challenging landscape, farmers are employing strategies such as cost management and operational optimization. One promising approach is to use modeling and simulation to optimize farm operations without substantial capital investment. Recent advances in computational methods have enabled sophisticated digital-twin frameworks for precision agriculture [2, 3], and machine learning techniques have been

72 applied to optimize sensor placement and resource delivery in agricultural
73 systems [4, 5].

74 Mathematical modeling of crop growth has a rich history, with models
75 ranging from simple empirical relationships to complex mechanistic simula-
76 tions. Logistic growth models, first proposed by Verhulst in 1838, remain
77 widely used due to their interpretability and ability to capture resource-
78 limited growth dynamics [6]. More sophisticated crop models such as DSSAT
79 [7], APSIM [8], and WOFOST [9] simulate detailed physiological processes
80 but require extensive parameterization and may be computationally expen-
81 sive for optimization applications. In contrast, reduced-order models that
82 capture essential dynamics while remaining tractable for optimization have
83 gained attention in precision agriculture [10].

84 Optimization of irrigation and fertilizer application has been studied us-
85 ing various approaches, including linear and nonlinear programming [11],
86 dynamic programming [12], and metaheuristic algorithms [13]. Genetic algo-
87 rithms (GAs) are particularly well-suited for this domain because they can
88 handle nonlinear, non-convex objective functions and do not require gradi-
89 ent information [14]. Previous work has applied GAs to irrigation scheduling
90 [15] and fertilizer optimization [16], but these studies often use simplified
91 plant response models that do not capture the delayed, cumulative effects of
92 resource application.

93 This paper presents a generalized, coupled ordinary differential equation
94 (ODE) model for crop growth that addresses these limitations. The model
95 captures: (1) nonlinear logistic growth with state-dependent carrying ca-
96 pacities, (2) delayed absorption of water, fertilizer, temperature, and solar
97 radiation inputs through finite impulse response (FIR) convolution, (3) cu-
98 mulative stress tracking via exponential moving average (EMA) filters, and
99 (4) coupling between vegetative and reproductive growth stages. The model
100 is designed to enable global optimization under delayed, resource-coupled
101 dynamics—a regime where even well-established management practices may
102 benefit from computational refinement due to the sheer number of possible
103 scheduling combinations.

104 We demonstrate the framework by optimizing irrigation and fertilizer
105 strategies for corn, the most widely planted crop in the United States by
106 acreage. Using a genetic algorithm, we search for strategies that maximize
107 net revenue (crop value minus input costs) over a growing season. The ap-
108 proach is validated using historical weather data from Fairfax, Iowa, a rep-
109 resentative location in the Corn Belt.

110 2. Generalized, coupled-ODE crop model

111 The proposed model tracks five state variables representing key aspects
 112 of plant development: plant height h (m), leaf area per leaf A (m²), num-
 113 ber of leaves N , flower size c (number of spikelets), and fruit biomass P
 114 (kg). Each state variable follows logistic growth dynamics with time-varying
 115 growth rates and carrying capacities that depend on environmental condi-
 116 tions and resource availability.

117 The model receives four input signals: water from irrigation w (inches),
 118 fertilizer application f (lbs), ambient temperature T (°C), and solar radiation
 119 R (W/m²). Precipitation S (inches) is added to irrigation to obtain total
 120 water input. Temperature and radiation data are obtained from the National
 121 Solar Radiation Database (NSRDB) [17], while precipitation data comes from
 122 NOAA historical records [18].

123 2.1. Delayed absorption via FIR convolution

124 Plants do not immediately process applied nutrients; instead, there is
 125 a physiologically-mediated delay between application and utilization. We
 126 model this delayed absorption using finite impulse response (FIR) convolu-
 127 tion with Gaussian kernels.

128 If cumulative nutrient uptake follows a sigmoid trajectory—with slow ini-
 129 tial uptake due to transport lag, rapid increase once metabolic pathways acti-
 130 vate, and eventual saturation—then instantaneous absorption rate follows a
 131 bell-shaped curve. A Gaussian kernel is the least assumptive choice for a bell
 132 curve, requiring only two parameters: the temporal spread σ (characterizing
 133 absorption duration) and the peak delay μ .

134 Given only the temporal spread σ for each nutrient type, we determine μ
 135 such that 95% of the kernel mass lies within $[0, 2\mu]$. This requires solving

$$\text{erf}\left(\frac{\mu}{\sigma\sqrt{2}}\right) = 0.95, \quad (1)$$

136 which yields $\mu \approx 1.96\sigma$. The Gaussian FIR kernel is then

$$g[k] = \frac{1}{\sqrt{2\pi}\sigma} \exp\left\{-\frac{1}{2}\frac{(k-\mu)^2}{\sigma^2}\right\}. \quad (2)$$

137 The FIR horizon L^* is chosen as the minimum length capturing 95% of
 138 the kernel mass:

$$L^* = \min_L \left\{ L : \frac{\sum_{k=0}^{L-1} g[k]}{\sum_{k=0}^{K-1} g[k]} \geq 0.95 \right\} \quad (3)$$

139 where K is the simulation length in hours.

140 Different nutrients have different metabolic timescales. We use $\sigma_w = 30$
 141 hours for water (rapid uptake), $\sigma_f = 300$ hours for fertilizer (slow uptake re-
 142 flecting root absorption dynamics), and $\sigma_T = \sigma_R = 30$ hours for temperature
 143 and radiation (immediate physiological effects with short memory).

144 2.2. Cumulative stress tracking via EMA filtering

145 While FIR convolution captures delayed absorption, plants also accumu-
 146 late stress from sustained deviations from optimal conditions. We model this
 147 cumulative effect using exponential moving average (EMA) filters, which are
 148 equivalent to first-order infinite impulse response (IIR) systems.

149 The EMA filter with memory parameter $\beta \in [0, 1)$ has the recursive form:

$$y[k] = (1 - \beta)x[k] + \beta y[k - 1] \quad (4)$$

150 where larger β values correspond to longer memory (slower response to
 151 changes). This formulation preserves constant signals ($x[k] = c$ implies
 152 $y[k] \rightarrow c$) while smoothing transient fluctuations.

153 2.3. Nutrient factor calculation

154 We now describe the complete transformation pipeline that converts raw
 155 input signals into nutrient factors $\nu \in [0, 1]$ that modulate plant growth. Us-
 156 ing fertilizer as an example (the same process applies to water, temperature,
 157 and radiation):

158 **Step 1: Delayed absorption.** Convolve the raw fertilizer signal $f[k]$
 159 with the Gaussian FIR kernel:

$$\bar{f}[k] = \sum_{n=0}^{L_f-1} g_f[n] f[k - n] \quad (5)$$

160 **Step 2: Cumulative absorption.** Compute the running sum of ab-
 161 sorbed fertilizer:

$$F[k] = \sum_{n=0}^k \bar{f}[n] \quad (6)$$

162 **Step 3: Instantaneous anomaly.** Compare actual cumulative absorp-
 163 tion to expected levels:

$$\delta_f[k] = \left| \frac{k \cdot f_{\text{typ}} - F[k]}{k \cdot f_{\text{typ}} + \epsilon} \right| \quad (7)$$

164 where f_{typ} is the typical hourly fertilizer level the plant “expects” and ϵ is a
 165 small constant preventing division by zero.

166 **Step 4: Cumulative divergence.** Apply EMA smoothing to track
 167 sustained anomalies:

$$\Delta_f[k] = \beta_\Delta \Delta_f[k-1] + (1 - \beta_\Delta) \delta_f[k] \quad (8)$$

168 where $\beta_\Delta = 0.95$ provides long memory.

169 **Step 5: Nutrient factor.** Convert divergence to a stress factor via
 170 exponential decay with additional EMA smoothing:

$$\nu_f[k] = \beta_\nu \nu_f[k-1] + (1 - \beta_\nu) \exp\{-\alpha \Delta_f[k]\} \quad (9)$$

171 where $\alpha = 3$ ensures $\nu \approx 0.05$ when $\Delta = 1$ (complete divergence from
 172 expected levels), and $\beta_\nu = 0.05$.

173 The nutrient factor $\nu_f[k]$ equals 1 when fertilizer application perfectly
 174 matches expected levels and decays toward 0 under sustained over- or under-
 175 application. This captures the intuition that plants are resilient to brief
 176 deviations but suffer cumulative damage from prolonged stress.

177 Figure 1 illustrates the FIR convolution and EMA smoothing operations
 178 that constitute the metabolic transformation pipeline. The left panel shows
 179 how the Gaussian FIR kernel spreads and delays input signals, while the
 180 right panel demonstrates how EMA filtering with different β values tracks
 181 cumulative divergence with varying memory lengths.

182 *2.4. Effects of inputs on plant growth*

183 Different inputs affect different aspects of plant growth. Tables 1 and 2
184 summarize these relationships based on agronomic literature [19, 20, 21].

State variable	Irrigation on growth rate	Fertilizer on growth rate	Irrigation on capacity	Fertilizer on capacity
Plant height h	\sim	+	\sim	+
Leaf area A	\sim	+	+	+
Number of leaves N	\sim	\sim	\sim	\sim
Flower size c	\sim	\sim	+	\sim
Fruit biomass P	\sim	\sim	+	+

Table 1: Effects of irrigation and fertilizer on growth dynamics. “+” indicates positive effect, “ \sim ” indicates a negligible effect.

State variable	Temp. on growth rate	Temp. on capacity	Radiation on growth rate	Radiation on capacity
Plant height h	+	+	+	+
Leaf area A	+	+	+	+
Number of leaves N	\sim	+	\sim	+
Flower size c	−	−	−	−
Fruit biomass P	+	+	+	+

Table 2: Effects of temperature and solar radiation on growth dynamics. “+” indicates positive effect, “ \sim ” indicates a negligible effect, “−” indicates a negative effect. For flower size, excess heat and radiation reduce flower development, hence negative effects.

185 *2.5. Growth dynamics*

186 Each state variable follows logistic growth with time-varying parameters
187 modulated by nutrient factors. The general form is:

$$\frac{dx}{dt} = \hat{a}_x(t) \cdot x(t) \left(1 - \frac{x(t)}{\hat{k}_x(t)} \right) \quad (10)$$

188 where $\hat{a}_x(t)$ is the effective growth rate and $\hat{k}_x(t)$ is the effective carrying
 189 capacity, both functions of the nutrient factors.

190 The effective parameters are computed as geometric means of the relevant
 191 nutrient factors, reflecting multiplicative rather than additive effects. This
 192 choice is motivated by the observation that growth rates compound over
 193 time, making geometric averaging appropriate [22].

194 **Plant height** responds to fertilizer, temperature, and radiation:

$$\hat{a}_h(t) = a_h(\nu_f \nu_T \nu_R)^{1/3}, \quad \hat{k}_h(t) = k_h(\nu_f \nu_T \nu_R)^{1/3} \quad (11)$$

195 **Leaf area** additionally depends on water and is coupled to height:

$$\hat{a}_A(t) = a_A(\nu_f \nu_T \nu_R)^{1/3}, \quad \hat{k}_A(t) = k_A \left(\nu_w \nu_f \nu_T \nu_R \frac{\hat{k}_h}{k_h} \right)^{1/5} \quad (12)$$

196 **Number of leaves** depends only on temperature and radiation through
 197 the carrying capacity:

$$\hat{a}_N(t) = a_N, \quad \hat{k}_N(t) = k_N(\nu_T \nu_R)^{1/2} \quad (13)$$

198 **Flower size** (spikelet count) exhibits inverse dependence on temperature
 199 and radiation—excess heat and light reduce flowering:

$$\hat{a}_c(t) = a_c \left(\frac{1}{\nu_T} \frac{1}{\nu_R} \right)^{1/2}, \quad \hat{k}_c(t) = k_c \left(\nu_w \frac{1}{\nu_T} \frac{1}{\nu_R} \right)^{1/3} \quad (14)$$

200 **Fruit biomass** depends on all inputs and is coupled to vegetative growth:

$$\hat{a}_P(t) = a_P \left(\frac{1}{\nu_T} \frac{1}{\nu_R} \right)^{1/2}, \quad \hat{k}_P(t) = k_P \left(\nu_w \nu_f \nu_T \nu_R \frac{\hat{k}_h}{k_h} \frac{\hat{k}_A}{k_A} \frac{\hat{k}_c}{k_c} \right)^{1/7} \quad (15)$$

201 The coupling terms \hat{k}_h/k_h , \hat{k}_A/k_A , and \hat{k}_c/k_c encode physiological depen-
 202 dencies: taller plants with more leaf area can support larger fruit, while larger
 203 tassels (more spikelets) may compete with ear development.

204 2.6. Model parameters

205 The baseline growth rates and carrying capacities are crop-specific pa-
 206 rameters that can be estimated from field data or literature values. For corn,
 207 we use the values in Table 3, calibrated to match typical development time-
 208 lines where plants reach full vegetative size around 65–70 days after sowing
 209 and grain fill completes around 125 days [23].

State	Growth rate	Carrying capacity	Initial condition	Units
Height h	$a_h = 0.010 \text{ hr}^{-1}$	$k_h = 3.0$	$h_0 = 0.001$	m
Leaf area A	$a_A = 0.0105 \text{ hr}^{-1}$	$k_A = 0.65$	$A_0 = 0.001$	m ²
Leaves N	$a_N = 0.011 \text{ hr}^{-1}$	$k_N = 20$	$N_0 = 0.001$	count
Spikelets c	$a_c = 0.010 \text{ hr}^{-1}$	$k_c = 1000$	$c_0 = 0.001$	count
Fruit P	$a_P = 0.005 \text{ hr}^{-1}$	$k_P = 0.25$	$P_0 = 0.001$	kg

Table 3: Baseline model parameters for corn. Growth rates are per hour; initial conditions are set to k_x/K where $K \approx 2900$ is the season length in hours.

210 3. Simulation

211 The logistic ODE admits a closed-form solution, enabling exact time-
212 stepping without numerical integration error. Given state $x(t)$ at time t , the
213 state at $t + \Delta t$ is:

$$x(t + \Delta t) = \frac{\hat{k}_x(t)}{1 + \left(\frac{\hat{k}_x(t)}{x(t)} - 1 \right) \exp(-\hat{a}_x(t)\Delta t)} \quad (16)$$

214 where $\hat{a}_x(t)$ and $\hat{k}_x(t)$ are treated as constant over the time step. This closed-
215 form approach is more accurate than forward Euler integration and avoids
216 instability issues that can arise with explicit methods at larger time steps.

217 We simulate the growing season at hourly resolution ($\Delta t = 1$ hour),
218 yielding approximately 2900 time steps for a typical corn season (late April
219 to early October). At each step, we: (1) update the nutrient factors based on
220 cumulative inputs and divergences, (2) compute effective growth rates and
221 carrying capacities, and (3) advance each state variable using Equation 16.

222 4. Optimization via genetic algorithm

223 Given the nonlinear, delay-affected dynamics of the crop model, gradient-
224 based optimization is challenging. The delayed effects of inputs create a
225 non-convex landscape with potentially many local optima. We therefore
226 employ a genetic algorithm (GA), a population-based metaheuristic inspired
227 by natural selection that can effectively explore complex search spaces [14].

228 *4.1. Decision variables*

229 Each candidate solution encodes a complete irrigation and fertilization
230 strategy as a four-dimensional vector:

$$\mathbf{u} = \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{bmatrix} = \begin{bmatrix} \text{irrigation frequency (hours)} \\ \text{irrigation amount (inches)} \\ \text{fertilizer frequency (hours)} \\ \text{fertilizer amount (lbs)} \end{bmatrix} \quad (17)$$

231 The frequencies specify application intervals: $u_1 = 168$ means irrigate
232 every 168 hours (weekly). The amounts specify the quantity applied at
233 each event. This parameterization assumes regular, periodic application—a
234 simplification that captures common agricultural practice while keeping the
235 search space tractable.

236 *4.2. Objective function*

237 The objective is to maximize net revenue, defined as crop value minus
238 input costs.

$$\text{Revenue}(\mathbf{u}) = \text{Crop Value} - \text{Input Costs} \quad (18)$$

239 The crop value depends on final plant state at harvest:

$$\text{Crop Value} = \omega_h h[K] + \omega_A A[K] + \omega_P P[K] \quad (19)$$

240 where K is the final time step and ω_h , ω_A , ω_P are economic weights (dollars
241 per unit) for height, leaf area, and fruit biomass respectively.

242 The input costs accumulate over the season:

$$\text{Input Costs} = \omega_w \sum_{k=0}^K w[k] + \omega_f \sum_{k=0}^K f[k] \quad (20)$$

243 where ω_w and ω_f are costs per unit of irrigation and fertilizer.

244 For corn, the economic weights are derived from market prices and typical
245 yields (Table 4). The fruit biomass weight dominates, reflecting that grain
246 yield is the primary economic output.

Parameter	Value	Derivation
ω_w	\$2.00/inch	Typical irrigation cost
ω_f	\$0.61/lb	Weighted NPK cost
ω_h	\$35/m	Silage value proxy
ω_A	\$215/m ²	Silage value proxy
ω_P	\$4,450/kg	\$4/bushel \times plant density

Table 4: Economic weights for the corn objective function. The fruit biomass weight accounts for approximately 28,350 plants per acre at \$0.157/kg.

247 4.3. Algorithm description

248 The GA maintains a population of M candidate solutions and iteratively
249 improves them through selection, crossover, and mutation over G genera-
250 tions. Algorithm 1 presents the complete procedure.

251 **Selection.** After each generation, population members are ranked by
252 cost. The top P members survive as “parents” for the next generation. This
253 selection ensures the best solutions are never lost.

254 **Crossover.** New “children” are created by blending two parent solutions.
255 For each child, we randomly select two parents and compute a weighted
256 average:

$$\mathbf{u}^{(\text{child})} = \phi \cdot \mathbf{u}^{(a)} + (1 - \phi) \cdot \mathbf{u}^{(b)} \quad (21)$$

257 where $\phi \sim \text{Uniform}(0, 1)$ under normal operation. This crossover can produce
258 children anywhere along the line segment connecting the parents, enabling
259 smooth exploration of the search space.

260 **Mutation and Diversity.** To maintain population diversity and escape
261 local optima, the remaining $M - P - C$ population slots are filled with ran-
262 domly generated solutions. Additionally, if the best cost stagnates (changes
263 by less than 0.01) for 10 consecutive generations, we switch to aggressive
264 crossover with $\phi \sim \text{Uniform}(-1, 2)$. This allows children to lie outside the
265 convex hull of their parents, promoting exploration of new regions.

266 **Default Parameters.** We use $M = 128$ members, $P = 16$ parents,
267 $C = 16$ children, and $G = 100$ generations. The large population relative
268 to generations ensures diversity for exploration while preventing premature
269 convergence.

270 5. Case study: corn in iowa

271 We demonstrate the framework using corn, the most widely planted crop
 272 in the United States with over 90 million acres harvested annually [24].
 273 The case study uses historical weather data from Fairfax, Iowa (41.76°N,
 274 91.87°W), a representative location in the Corn Belt (USDA climate zones
 275 4b–5b).

276 5.1. Scenario configuration

277 The simulation covers a typical growing season from late April to early
 278 October (approximately 2900 hours). Environmental inputs are:

- 279 • **Temperature and radiation:** Hourly data from NSRDB for Fairfax,
 280 IA. Mean temperature is 22.8°C; mean solar radiation is 580 W/m².
- 281 • **Precipitation:** Daily data from NOAA, interpolated to hourly reso-
 282 lution.
- 283 • **Typical nutrient expectations:** Based on agronomic recommenda-
 284 tions [25], the model expects 28 inches of water and 355 lbs of NPK
 285 fertilizer over the season ($w_{\text{typ}} \approx 0.01$ in/hr, $f_{\text{typ}} \approx 0.12$ lb/hr).

286 Table 5 summarizes expected corn development timelines used to calibrate
 287 model parameters.

State variable	Days to maturity	Hours to maturity	Typical final value
Plant height h	65–70	1560–1680	2.7–3.7 m
Leaf area A	55–65	1320–1560	0.6–0.7 m ²
Number of leaves N	65	1560	18–20
Spikelets c	65–70	1560–1680	~1000
Fruit biomass P	125	3000	0.15–0.36 kg

Table 5: Corn development timeline and typical final values from agronomic literature [23, 26].

288 *5.2. Baseline scenario: farmer best practices under drought*

289 To establish a performance baseline, we first simulate crop growth under
290 a drought scenario (50% of typical precipitation) using conventional farmer
291 practices: weekly irrigation of 1 inch [27] and monthly fertilizer applications
292 of 90 lbs [28]. These values reflect standard agronomic recommendations for
293 corn in the Corn Belt region.

294 Figure 2 shows the environmental disturbances and control inputs over the
295 growing season. The reduced precipitation characteristic of a drought year is
296 clearly visible, along with the periodic irrigation and fertilizer applications.

297 Figure 3 shows the resulting plant state trajectories. Under drought con-
298 ditions with conventional management, the plant reaches the following final
299 values: height of 2.6 m (vs. 3.0 m capacity), leaf area of 0.57 m² (vs. 0.65
300 m²), and fruit biomass of 0.22 kg (vs. 0.25 kg). The net revenue under this
301 baseline scenario is \$859/acre.

302 The baseline scenario demonstrates how the model captures stress ef-
303 fects: despite regular irrigation, the mismatch between applied water and
304 the plant’s metabolic expectations under drought conditions leads to sus-
305 tained nutrient factor depression and reduced growth potential. Detailed
306 visualizations of the applied vs. absorbed nutrients, cumulative values, and
307 nutrient factors are provided in the Supplementary Information.

308 5.3. Optimization configuration

309 The GA searches over the following bounds:

- 310 • Irrigation frequency: 100–700 hours (4–29 days between applications)
- 311 • Irrigation amount: 0.5–5.0 inches per application
- 312 • Fertilizer frequency: 700–2900 hours (29–121 days, i.e., 1–4 applications
313 per season)
- 314 • Fertilizer amount: 100–500 lbs per application

315 These bounds reflect practical constraints: irrigation systems have mini-
316 mum application rates, and fertilizer is typically applied in a small number of
317 large doses rather than continuously. The optimization was performed under
318 the same environmental conditions: a drought scenario with 50% of typical
319 precipitation.

320 5.4. Optimization results

321 To assess robustness of the optimization, we executed 10 independent
322 GA runs with different random seeds. Figure 4 shows the convergence of
323 all 10 runs, with each curve representing the best revenue achieved at each
324 generation. All runs converge to similar final values (within 3% of each other),
325 demonstrating that the GA reliably finds near-optimal solutions despite the
326 stochastic nature of the search.

327 The optimal strategy identified by the GA is summarized in Table 6.
328 Notably, the algorithm discovers a strategy with less frequent but larger
329 irrigation events and infrequent fertilizer applications—a pattern that mini-
330 mizes cumulative divergence from expected nutrient levels given the model’s
331 delayed absorption dynamics.

Parameter	Optimal Value	Interpretation
Irrigation frequency	1237 hours	Every ~ 7 weeks
Irrigation amount	5 inches	Per application
Fertilizer frequency	803 hours	Every 33 days
Fertilizer amount	77 lbs	Per application

Table 6: Optimal irrigation and fertilization strategy identified by the GA.

332 Figure 5 shows the plant state trajectories for the best member in each of
333 the 10 GA runs. All optimized strategies achieve substantially higher final
334 values than the baseline farmer practices: fruit biomass ranges from 0.168–
335 0.225 kg (vs. 0.22 kg baseline), heights reach 2.41–2.88 m (vs. 2.6 m), leaf
336 areas reach 0.44–0.56 m² (vs. 0.57 m²), and revenues reach 778–999 \$/acre
337 (vs. \$859/acre baseline). The consistency across runs further confirms the
338 robustness of the optimization, and while the farmer best practice yields
339 higher revenue than one GA run (run 2), in aggregate, the GA optimization
340 meaningfully improved upon the baseline.

341 Table 7 provides an economic comparison between the baseline farmer
342 practices and the GA-optimized strategies. The best GA strategy achieves
343 \$999/acre net revenue compared to \$859/acre for the baseline—a 16% im-
344 provement. Even the worst members in each GA run’s final population out-
345 perform the baseline, providing a sanity check that random strategies are not
346 viable (see Supplementary Information).

Metric	GA-Optimized	Baseline
Final fruit biomass	0.22 kg	0.22 kg
Final height	2.8 m	2.6 m
Final leaf area	0.60 m ²	0.57 m ²
Total irrigation	15 inches	18 inches
Total fertilizer	307 lbs	450 lbs
Crop value	\$1218	\$1171
Input costs	\$219	\$312
Revenue	\$999	\$859

Table 7: Economic comparison of GA-optimized versus baseline farmer strategies. The optimized strategy achieves 16% higher net revenue through both increased crop value and dramatically reduced irrigation costs.

347 6. Discussion

348 6.1. Interpretation of results

349 The GA-optimized strategy differs from conventional wisdom in several
350 notable ways. The algorithm discovers that less frequent but larger irrigation
351 events, combined with reduced total fertilizer input, can outperform conven-
352 tional uniform application schedules. This counterintuitive result emerges
353 from the model’s delayed absorption dynamics: under drought conditions,
354 the plant’s metabolic expectations are calibrated to typical water availabil-
355 ity. The GA discovers that strategically-timed resource inputs better main-
356 tain alignment with metabolic expectations than aggressive compensation
357 for drought through frequent, uniform applications.

358 The consistency across 10 independent GA runs provides confidence that
359 the optimization reliably identifies high-performing regions of the strategy
360 space. While individual runs converge to somewhat different local optima
361 (with revenues ranging from \$778 to \$983 per acre), 9 of 10 runs outperform

the baseline farmer practices, demonstrating the robustness of the optimization approach. The sanity check showing that even the worst members in each final population generally outperform baseline practices confirms that the GA successfully eliminates poor candidates.

The 16% revenue improvement (\$999 vs. \$859 per acre) demonstrates substantial potential value from model-based optimization. This improvement comes from two sources: (1) increased crop value due to better-aligned nutrient delivery, and (2) reduced input costs. The result suggests that conventional wisdom about drought response—applying more water to compensate—may be suboptimal when plant physiology involves delayed, cumulative-effect dynamics.

6.2. Parameter estimation in practice

The framework requires crop-specific parameters: growth rates, carrying capacities, metabolic timescales, and typical nutrient expectations. Several approaches could estimate these from data:

- **Growth curves:** Time-series imagery from field cameras or drones, processed with computer vision, could provide height and leaf area trajectories for fitting a_x and k_x parameters.
- **Metabolic timescales:** The temporal spreads σ could be estimated from controlled experiments varying input timing, or inferred from physiological literature on nutrient uptake rates.
- **Typical expectations:** Regional agronomic recommendations provide baseline values for w_{typ} , f_{typ} , T_{typ} , and R_{typ} .

Physics-informed neural networks (PINNs) could jointly fit model parameters and approximate unknown functional forms in the dynamics, potentially relaxing some of the structural assumptions in Section 2.

6.3. Limitations and extensions

Several model limitations suggest directions for future work:

Growth model. The logistic equation assumes symmetric growth around the inflection point. Richards growth [29] generalizes this with a shape parameter ν :

$$\frac{dx}{dt} = a_x x \left[1 - \left(\frac{x}{k_x} \right)^\nu \right] \quad (22)$$

393 where $\nu > 1$ produces steeper early growth (common in vegetative stages)
394 and $\nu < 1$ produces steeper late growth.

395 **Absorption kernels.** Gaussian kernels are symmetric, but physiological
396 absorption often exhibits fast activation followed by slow decay. Log-normal
397 or Gamma kernels could better capture this asymmetry.

398 **Saturation.** The current model does not explicitly limit nutrient uptake—
399 all applied inputs eventually affect the plant. In reality, excess application
400 may be lost to runoff or leaching. Saturating nonlinearities in the absorption
401 pathway would provide a more realistic response to over-application.

402 **Spatial heterogeneity.** The model treats a single representative plant.
403 Field-scale optimization would need to account for spatial variation in soil
404 properties, microclimate, and plant density.

405 **Stochastic weather.** The case study uses historical weather data. Ro-
406 bust optimization under weather uncertainty, or adaptive strategies that re-
407 spond to observed conditions, could improve real-world performance.

408 7. Conclusion

409 This paper presented a coupled ODE model for crop growth that cap-
410 tures delayed nutrient absorption via FIR convolution and cumulative stress
411 effects via EMA filtering. The model’s time-varying growth rates and carry-
412 ing capacities encode the intuition that plant development depends not just
413 on current conditions but on the history of resource availability relative to
414 physiological expectations.

415 Applied to corn optimization in Iowa under drought conditions, a ge-
416 netic algorithm discovered irrigation and fertilizer strategies that achieve
417 16% higher net revenue than conventional farmer practices (\$999 vs. \$859
418 per acre). This improvement emerges from the model’s delayed absorption
419 dynamics: strategic timing of inputs that aligns with metabolic expectations
420 outperforms uniform application schedules. The consistency across 10 inde-
421 pendent optimization runs, with 9 of 10 outperforming the baseline, confirms
422 the robustness of these findings.

423 The framework is generalizable to other crops through re-parameterization
424 and offers a computationally tractable approach to input optimization. Fu-
425 ture work will extend the model to handle weather uncertainty, incorporate
426 spatial heterogeneity, and validate predictions against field trial data.

427 8. Supplementary information

428 This supplementary section provides additional visualizations of the base-
429 line scenario (farmer best practices under drought) and the GA optimization
430 results.

431 *S1. Detailed baseline scenario analysis*

432 Figure 6 shows the applied versus absorbed nutrients under the baseline
433 scenario. The delayed absorption via FIR convolution is clearly visible: the
434 absorbed signals (smoothed curves) lag behind the applied inputs and exhibit
435 the characteristic spreading effect of the Gaussian kernels.

436 Figure 7 shows the cumulative absorbed nutrients compared to expected
437 (typical) levels. Under drought conditions, actual water absorption falls pro-
438 gressively below expectations, while fertilizer, temperature, and radiation
439 track more closely to typical values.

440 Figure 8 shows the instantaneous divergence from expected cumulative
441 levels. These divergences, after EMA smoothing, determine the nutrient
442 factors that modulate plant growth.

443 Figure 9 shows the resulting nutrient factors. The water factor ν_w declines
444 throughout the season as drought stress accumulates, reaching approximately
445 0.6 by harvest. This reduced water factor is the primary driver of the sub-
446 optimal crop growth observed in the baseline scenario.

447 *S2. GA optimization: worst-case analysis*

448 As a sanity check, Figure 10 shows the plant state trajectories for the
449 *worst* member in each GA run’s final population. Even these subopti-
450 mal strategies—the least fit survivors after 100 generations of evolution—
451 outperform the baseline farmer practices. This confirms that: (1) the GA
452 successfully eliminates poor strategies, and (2) random or arbitrary irri-
453 gation/fertilization schedules cannot match even the worst optimized ap-
454 proaches.

Figure 1: Illustration of the metabolic transformation pipeline. Panel 1: Gaussian FIR kernels with different temporal spreads σ demonstrate how water ($\sigma_w = 30$ hr) is absorbed more rapidly than fertilizer ($\sigma_f = 300$ hr). Panel 4: EMA filters with different memory parameters β show how cumulative divergence tracking responds to sustained anomalies, with larger β providing longer memory of past stress events.

Hourly Disturbances and Control Inputs

Figure 2: Environmental disturbances and control inputs for the baseline scenario. Top three panels show hourly precipitation (reduced to 50% of normal), solar radiation, and temperature from historical Iowa data. Bottom two panels show the farmer's irrigation (weekly, 1 inch) and fertilizer (monthly, 90 lbs) application strategy.

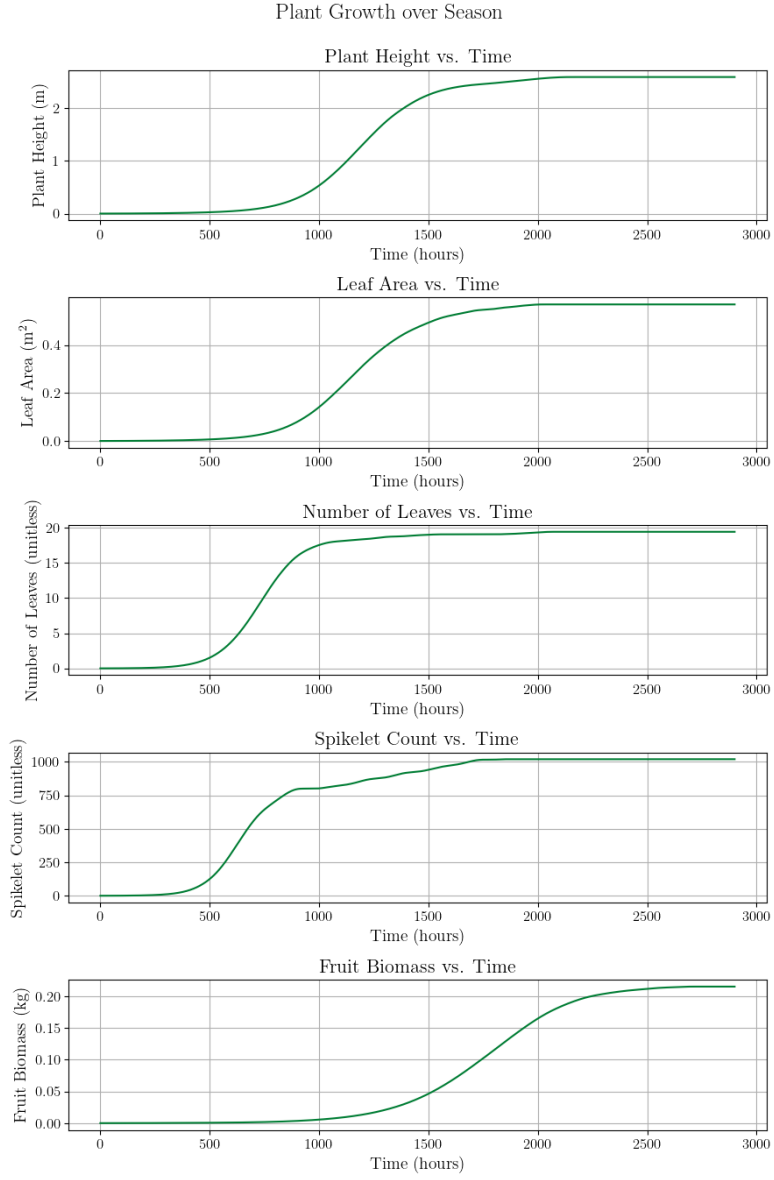

Figure 3: Plant state variable trajectories under the baseline scenario (farmer best practices during drought). All state variables reach suboptimal final values due to cumulative water stress. This strategy yields \$859/acre in revenue.

Figure 4: GA convergence across 10 independent runs. Each curve shows the best revenue at each generation. All runs exhibit rapid improvement in early generations followed by convergence to near-optimal solutions. The consistency across runs demonstrates algorithm robustness.

Figure 5: Plant state variable trajectories for the best member from each of the 10 independent GA runs. All optimized strategies achieve similar, near-optimal growth trajectories, and 9 of 10 runs substantially outperform the baseline farmer practices (Figure 3). The tight clustering of trajectories demonstrates that different GA runs converge to similar optimal strategies.

Applied and Absorbed Inputs and Disturbances over Season

Figure 6: Applied versus absorbed nutrients under the baseline farmer strategy. The delayed absorption dynamics are evident in the lag between applied inputs and the smoothed absorbed signals. Water absorption ($\sigma_w = 30$ hr) responds more quickly than fertilizer absorption ($\sigma_f = 300$ hr).

Figure 7: Cumulative absorbed nutrients (solid) versus expected levels (dashed red). The growing gap between actual and expected water absorption reflects the drought stress accumulating over the season. Fertilizer applications maintain closer alignment with expectations.

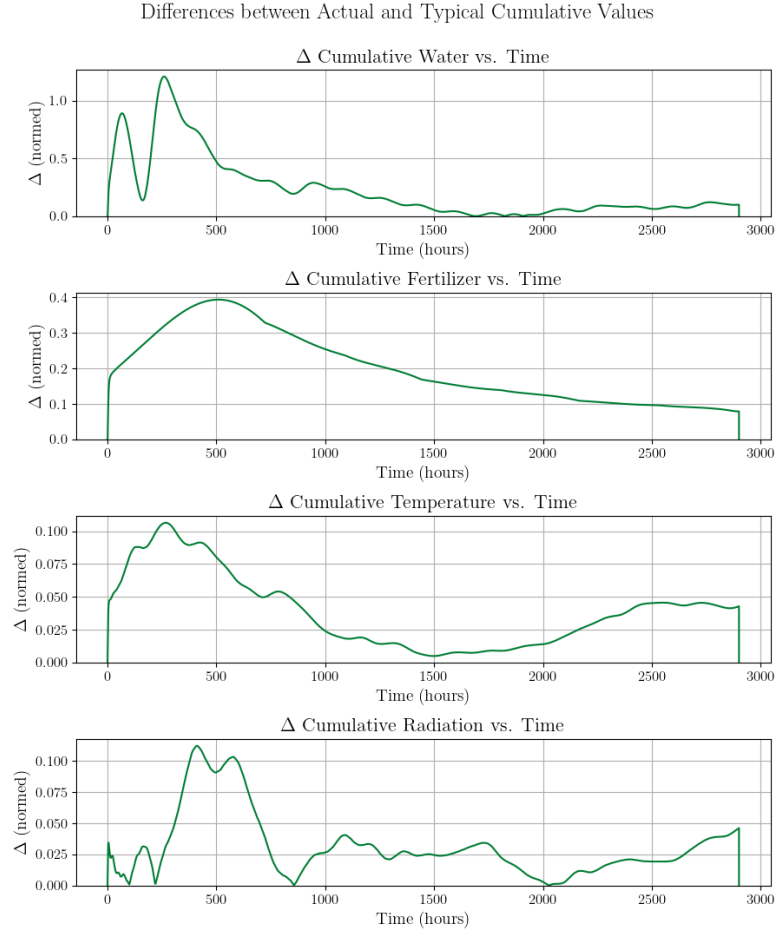

Figure 8: Instantaneous divergence from expected cumulative nutrient levels. Higher divergence indicates greater stress. The water divergence grows throughout the season due to cumulative drought effects.

Figure 9: Nutrient factor evolution under the baseline scenario. The water factor ν_w declines due to cumulative drought stress, while fertilizer, temperature, and radiation factors remain closer to 1.0 (no stress). The declining ν_w reduces effective growth rates and carrying capacities throughout the season.

Figure 10: Plant state variable trajectories for the worst member from each GA run's final population. Even these suboptimal strategies outperform baseline farmer practices (compare to Figure 3), demonstrating that the GA successfully identifies the high-performing region of the strategy space and that random strategies are not competitive.
